Abstract

Moths and butterflies (Lepidoptera) communities were investigated in the post-harvested valley peat bog Soumarský Most in the Bohemian Forest during vegetation season of 2011–2016. Total 371 species of all peat bog ecological categories were recorded. The survival of moths and butterflies was interpreted under natural vegetation succession and revitalization. The Soumarský Most bog seems to be colonized by bog insect specialists (tyrphobionts and tyraphophiles) from surrounding pristine peatlands of the Vltavský Luh complex (including the Mrtvý Luh bog), which is the unique source of recolonization by relict taxa. Only small insect species proportion probably survived the heavy peat exploitation of the Soumarský Most bog in the past time.

Key words: moths, butterflies, peat bog, ecological succession, conservation, Šumava Mountains, Vltavský Luh reserve

INTRODUCTION

Peat bogs of central Europe are relict unique ecosystems existing continuously since the early Holocene period at the same sites. The conservation priorities are the virgin and semi-virgin localities in South Bohemia, namely the peat bogs of the Bohemian Forest (Šumava Mountains) – cf. SCHREIBER (1924), BUFKOVÁ et al. (2005), SPITZER & DANKS (2006), SPITZER & BUFKOVÁ (2013). The extrazonal character of such peat bogs considering the existence of a large zone of similar peatland ecosystems in the North and Northeast Europe, gives the central European peat bogs a large biogeographical context in entomofauna and vegetation (for the list of Lepidoptera and bibliography see SPITZER & DANKS 2006, JAROŠ et al. 2014).

The most important human-made impacts are change of hydrological conditions, extraction of horticulture peat, and forest plantations. Even in the Bohemian Forest are some localities disturbed by human activities. The most important conservation of pristine peatlands needs supplementary projects of restoration ecology including studies of insect bioindicators. The extremely useful seems to be the Soumarský Most bog, which is under a project of revitalization and restoration of hydrological conditions. Hydrology of the Soumarský Most bog was disturbed several times for peat exploitation and forest management (LANTA et al. 2004, HORN 2009, HORN & BASTL 2012). Data of insect bioindicators (namely Lepidoptera) associated with restoration of the Soumarský Most bog are badly needed in continuation of our previous research in virgin/semivirgin peat bogs of the Bohemian Forest.

MATERIAL AND METHODS

Study site

All revised Lepidoptera records from the Soumarský Most bog were noted (2011–2016) in two basic revitalized units of wet and dry parts of the investigated bog (cf. HORN 2009). The locality Soumarský Most bog is a large peat bog (90 ha) – 48°54'N 13°50'E, altitude 745 m a.s.l. The original climax formation had to be association *Pino rotundatae-Sphagnetum* Kästner et Flössner 1933, surrounded by association *Vaccinio uliginosi-Pinetum* Kleist 1949. But only small fragments survived after large scale peat exploitation (HORN 2009). The locality is a part of the large wetland complex Vltavský Luh with several well preserved and mostly pristine valley peat bogs, e.g. the Mrtvý Luh bog (cf. BUFKOVÁ et al. 2005, SPITZER & BUFKOVÁ 2013, JAROŠ et al. 2014). First original description of vegetation was published by SCHREIBER (1924) with notes about partial bog exploitation. The impact of peat exploitation was extremely strong between 1958–1999 (LANTA et al. 2004, HORN 2009). The vegetation of the Soumarský Most bog before revitalization and restoration was described by HORN (2009) who recorded also plant colonization of a peat barren ground. From entomological point of view, the most important have been improvement of hydrological conditions and introduction of basic peat plants: *Sphagnum* spp., *Eriophorum* spp., and *Carex rostrata* (Fig. 1, cf. HORN 2009). Relatively rare records of *Vaccinium* spp. (namely *V. uliginosum*, Fig. 2) form food plants complex for some typhobiontic and typhophilous insects.

Surveys

The species of Lepidoptera were studied for a period 2011–2016. The main method of sampling moths was UV light trapping by modified Pennsylvanian light trap (8 W UV lamp). The light was placed directly on the ground. Diurnally active butterflies and moths were sampled by netting. Larvae were collected from food plants individually and reared in the laboratory. Nomenclature of Lepidoptera follows JAROŠ et al. (2014).

The four basic ecological categories were used (see e.g. MIKKOLA & SPITZER 1983, SPITZER & DANKS 2006): (1) typhobiontic species – bog specialists (stenotopic cold-adapted species of bogs); (2) typhophilous species (characteristic for bog, but not confined to them, more abundant on bogs than in adjacent habitat); (3) typhoneutral species (resident in bogs, but also common in other habitats); (4) typhoxenous species (non resident vagrants, often migratory species that cannot live permanently in bogs).

RESULTS AND DISCUSSION

During our five-year study, 371 species and 2758 individuals of Lepidoptera were recorded: ten species of which are typhobionts, 27 species typhophilous, 281 species typhoneutral, and 53 typhoxenous species (Appendix 1). Our results of the Soumarský Most bog conforms low number of typhobiontic species and high proportion of typhophiles and typhoneutrals (cf. JAROŠ et al. 2014). Typhoxens are associated with early succession and/or temporary colonization by migrants from other habitat (Appendix 1 – e.g. *Eurrhypara hortulata* and *Inachis io*). The most abundant are typhoneutrals in all stages of the succession, wet and dry habitats (see Appendix 1).

From conservation point of view, the most interesting groups are typhobionts, which are recorded from pristine bogs, some taxa are common in the nearest large peat bog Mrtvý Luh and adjacent localities. All the Mrtvý Luh moth populations of typhobionts are more diverse and abundant compared to Soumarský Most bog populations with exception of *Amphipoea lucens* associated with wet peaty grasslands (see ELSNER et al. 1981, SPITZER &

Fig. 1. The Soumarský Most bog (May 2011) – communities of natural peatland succession, dominant succession of *Eriophorum vaginatum*.

Fig. 2. The Soumarský Most bog (July 2016) – relatively rare communities of *Vaccinium uliginosum*.

Total number of typhobiontic species		10	24	17

DANKS 2006, JAROŠ et al. 2014, and Table 1). *Glyptipteryx haworthana* (Figs. 3,4) and *Celaena haworthii* are species with high probability associated with early succession of *Eriophorum* spp. and expanding *Sphagnum* cover after revitalization. Several other typhobionts are characteristic for drier habitats of relict *Vaccinium uliginosum*, which is the food plant of *Colias palaeno*. Already ELSNER et al. (1981) recorded several peatland Lepidoptera from the Soumarský Most bog including the typhobiontic moth *Crambus alienellus*, which disappeared after heavy exploitation and disturbance of water system of the bog. Some forest species (F in Appendix 1) are also associated with *Vaccinium* formations. The typhophiles are often common (Appendix 1), some are important for conservation and rare outside peatlands. The only exception is *Crambus uliginosellus* discovered in the Soumarský Most bog, which is a rare species in Czechia and has only one locality in the Bohemian Forest (Appendix 1).

Fig. 3. *Eriophorum vaginatum* and freshly emerged male of *Glyptipterix haworthana*, the Soumarský Most bog, 10 May 2012.

Fig. 4. *Glyptipterix haworthana* is common in all peatlands near Soumarský Most (e.g. the Velká Niva bog, 16 May 2013) and strongly associated with the *Sphagnum* and *Eriophorum* spp. complex.

CONCLUSIONS

Revitalization of the Soumarský Most bog (see HORN 2009) seems to be important from lepidopterological point of view. Most of the species colonize the locality (wet parts especially) from near virgin peatlands (Mrtvý Luh bog, Malá Niva bog and some peaty fragments, “stepping stones” for some biota). If the revitalization of the Soumarský Most bog is successful, the territory of the large reserve Vltavský Luh will be completed. The whole Vltavský Luh reserve is one of the most important parts of the core zone of the Šumava National Park with unique Lepidoptera. The preservation of peatland hydrological conditions and elimination of closed spruce forest vegetation are basic implementations for conservation of relict insects, not only butterflies and moths (SPITZER & DANKS 2006).
